Summary
Here, we show that a small-molecule activator of telomerase (TA-65) purified from the root of Astragalus membranaceus is capable of increasing average telomere length and decreasing the percentage of critically short telomeres and of DNA damage in haploinsufficient mouse embryonic fibroblasts (MEFs) that harbor critically short telomeres and a single copy of the telomerase RNA Terc gene (G3 Terc−/− MEFs). Importantly, TA-65 does not cause telomere elongation or rescues DNA damage in similarly treated telomerase-deficient G3 Terc−/− littermate MEFs. These results indicate that TA-65 treatment results in telomerase-dependent elongation of short telomeres and rescue of associated DNA damage, thus demonstrating that TA-65 mechanism of action is through the telomerase pathway. In addition, we demonstrate that TA-65 is capable of increasing mouse telomerase reverse transcriptase levels in some mouse tissues and elongating critically short telomeres when supplemented as part of a standard diet in mice. Finally, TA-65 dietary supplementation in female mice leads to an improvement of certain health-span indicators including glucose tolerance, osteoporosis and skin fitness, without significantly increasing global cancer incidence.

Key words: telomerase activation; TA-65; telomere length; aging; mouse.

Introduction
Progressive attrition of telomeres is one of the best understood molecular changes associated with organismal aging in humans (Harley et al., 1990) and in mice (Flores et al., 2008). Telomeres are specialized structures at the ends of chromosomes, with an essential role in protecting the chromosome ends from fusions and degradation (Blackburn, 2001; de Lange, 2005). Mammalian telomeres consist of TTAGGG repeats bound by a six-protein complex known as shelterin (de Lange, 2005). A minimum length of TTAGGG repeats and the integrity of the shelterin complex are necessary for telomere protection (Blackburn, 2001; de Lange, 2005). Telomerase is a cellular reverse transcriptase (TERT, telomerase reverse transcriptase) capable of compensating telomere attrition through de novo addition of TTAGGG repeats onto the chromosome ends by using an associated RNA component as template (Terc, telomerase RNA component) (Greider & Blackburn, 1985). Telomerase expression can be detected in a number of adult cell types, including peripheral lymphocytes and adult stem cell compartments; however, this is not sufficient to maintain telomere length with age in most human and mouse tissues (Blasco et al., 1997; Harley, 2005; Flores et al., 2008). Further supporting the notion that telomerase levels may be rate-limiting for organismal aging, some diseases characterized by premature loss of tissue renewal and premature death, such as dyskeratosis congenita, aplastic anemia and idiopathic pulmonary fibrosis, are linked to germline mutations in Tert and Terc genes, which result in decreased telomerase activity and accelerated telomere shortening (Mitchell et al., 1999; Vulliamy et al., 2001; Yamaguchi et al., 2005; Armanios et al., 2007; Tsakiri et al., 2007). A role for telomerase in tissue renewal and organismal lifespan is also supported by telomerase-deficient (Terc−/−) mice (Blasco et al., 1997). These mice show progressive telomere shortening from the first generation (G1) until the third (G3) or fourth (G4) generation when in a pure C57BL6 background by which stage they present critically short telomeres, defective stem cell proliferative capacity, infertility because of germ cell apoptosis and increased genomic instability (Blasco et al., 1997; Herrera et al., 1999; Flores et al., 2005). We and others have shown that restoration of telomerase activity in these mice, by reintroduction of one copy of the Terc gene, rescues critically short telomeres and reverses chromosomal instability and cell and tissue defects associated with late-generation telomerase deficiency, including rescue of stem cell dysfunction and of organismal lifespan (Hemann et al., 2001a; Samper et al., 2001a; Siegl-Cachedenier et al., 2007). These studies illustrate that telomerase is preferentially recruited to the shortest telomeres, similarly to that shown for budding yeast (Teixeira et al., 2004), thereby ensuring chromosomal stability and tissue fitness. Importantly, these findings also suggested that therapies aimed to re-activate telomerase and...
Fig. 1 TA-65 rescues short telomeres in a telomerase-dependent manner. (A) Scheme of mouse crosses. (B) Telomerase activity was measured in mouse embryonic fibroblasts (MEFs) extracts grown in the presence or absence of TA-65 for 24 h and 5 days. The indicated concentrations of TA-65 were tested. A cellular extract from HCT116 cells was included as a positive control, and RNase was added in all experimental settings as negative control. IC, PCR efficiency control. (C) Quantification of telomere repeat amplification protocol assay values is expressed in fold changes of TA-65-treated cells compared to DMSO-treated controls. At least four independent experiments were used per condition. The mean amounts of telomerase activity and error bars (standard deviation) in the control. (C) Quantification of telomere repeat amplification protocol assay values is expressed in fold changes of TA-65-treated cells compared to DMSO-treated controls. At least four independent experiments were used per condition. The mean amounts of telomerase activity and error bars (standard deviation) in the control. TA-65 elongates short telomeres and increases health span of adult/old mice, B. B. de Jesus et al.

elongate short telomeres with age could have significant anti-aging effects. In this regard, we recently demonstrated that enhanced telomerase activity in mice overexpressing TERT is able to delay aging and extend the median lifespan by 40%, when combined with increased cancer resistance (Tomas-Loba et al., 2008).

Here, we report on our initial findings on the mechanism of action of TA-65, a small-molecule telomerase activator derived from an extract of a plant commonly used in traditional Chinese medicine, Astragalus membranaceous. TA-65 was identified in an empirical screen based on its ability to upregulate basal telomerase activity levels in neonatal human keratinocytes and has been studied in humans as a dietary supplement (Harley et al., 2010) leading to a decline of senescent and natural killer cells together with a significant reduction in the percentage of cells with short telomeres. Telomerase activation data and functional studies on a related molecule from this plant have been recently reported (Fauce et al., 2008). In that study, human immune cells were exposed ex vivo to the activator, and this resulted in significant telomere elongation and enhanced proliferative capacity of these cells. Here, we demonstrate that TA-65 is capable of increasing telomerase activity and elongating critically short telomeres in a telomerase-dependent manner in mouse embryonic fibroblasts (MEFs) haploinsufficient for the telomerase RNA component and in vivo, when supplemented as part of a standard diet in mice. We also report initial findings on the outcomes of a TA-65 dietary supplementation in female mice, and how it leads to an improvement of certain health-span indicators. Importantly, treatment with TA-65 did not show any detectable negative secondary effects, including no increase in the incidence of cancer.

Results

TA-65 stimulates telomerase activity and leads to telomerase-dependent elongation of short telomeres and rescue of DNA damage in MEF haploinsufficient for the telomerase RNA component

TA-65 has been identified as an effective telomerase activator in human immune cells, and neonatal keratinocytes and fibroblasts (Fauce et al., 2008; Harley et al., 2010). To delineate whether TA-65 could also have an impact on telomerase-dependent telomere extension, we tested its capacity to affect the length of...
Continued.

The shortest telomeres, which are the known preferred substrates of telomerase (Bianchi & Shore, 2007; Sabourin et al., 2007), in an ex vivo model haploinsufficient for telomerase. To this end, we crossed Terc−/+ female mice with G2 Terc−/− male mice to generate littermate populations of MEFs that were either G3 Terc−/+ or G3 Terc+/− (hereafter referred to as G3 Terc−/+ or G3 Terc+/− MEFs, respectively). The G3 progeny of these crosses inherit a set of chromosomes with short telomeres from the male Terc−/− parent and a set of chromosomes with normal telomeres from the female Terc+/− parent (Fig. 1A, scheme). Noteworthy that only the G3 Terc+/− progeny will inherit a copy of the Terc gene and, thereafter, is telomerase proficient (Fig. 1A). Using a telomere repeat amplification protocol assay (TRAP), we confirmed that reintroduction of the Terc allele successfully reconstituted telomerase activity in G3 Terc−/+ cells, while G3 Terc−/− littermates persisted telomerase negative (Figs 1B and S1). Importantly, 10 μM of TA-65 significantly increased telomerase TRAP activity at 24 h post-treatment in G3 Terc−/+ MEFs haploinsufficient for the telomerase RNA component, and this effect was lost 5 days post-treatment (Figs 1B and S1), possibly owing to fast kinetics of the compound or to the existence of negative feedback mechanisms. The observed telomerase stimulation is consistent with previous results with human keratinocytes (Harley et al., 2010). These results
TA-65 elongates short telomeres and increases health span of adult/old mice, B. B. de Jesus et al. 5

demonstrate that TA-65 is capable of activating telomerase by approximately 2-fold in primary MEFs haploinsufficient for telomerase activity.

The absence of telomerase in MEFs leads, among other phenotypes, to an increase in the percentage of short telomeres and ‘signal-free ends’ and the correlated appearance of chromosomal instability (Blasco et al., 1997; Herrera et al., 1999; Samper et al., 2001a; Cayuela et al., 2005). By using the quantitative telomere fluorescence in situ hybridization (Q-FISH) assay, we could observe that control telomerase reconstituted G3 Terc+ cells treated with 0.1% DMSO present a significant decrease in ‘signal-free’ ends (12.3–4.8%; Fig. 1D–H) and critically short telomeres (telomeres with < 8 kb length) compared to similarly treated G3 Terc−/− littermates (12.8–5.4% Fig. 1D–H). Treatment of telomerase-proficient G3 Terc+ cells with TA-65 during 5 days at concentrations of 1 or 10 μM resulted in an additional decrease in the percentage of signal-free ends to 1.6% and 2.9%, and short telomeres to 1.9% and 3.3%, respectively, compared to their control situation (0.1% DMSO) (Fig. 1D,F). In marked contrast, TA-65-treated G3 telomerase-deficient Terc−/− littermate MEFs presented similar number of short telomeres or ‘signal-free ends’ confirming the telomerase-

Fig. 2 TA-65 treatment of mice leads to increased TERT expression in vivo. (A) Scheme of the TA-65 treatment plan. (B) Fold change in mouse telomerase reverse transcriptase (mTERT) mRNA levels in different tissues from TA-65-treated mice of the 2-year-old group compared to untreated controls at 3 month post-treatment. mTERT mRNA values were normalized to actin. Student’s t-test was used for statistical comparisons. (C) Fold change in mTERT protein levels in liver extracts from 2-year-old mice treated or not with TA-65 (NS: nonspecific band) using an mTERT antibody previously validated by us (Martinez et al., 2010). As controls, mTERT protein expression is detected in wild-type mouse embryonic fibroblasts (MEFs) but not in TERT−/− MEFs (Liu et al., 2000). Quantification of mTERT expression is presented in the right panel (fold changes in TERT levels compared to the values obtained in the control situation (without TA-65)). The quantification was made with Scion Image Software. Student’s t-test was used for statistical comparisons. (D) Fold change in JunB mRNA levels at 3 months post-treatment in different tissues from 2-year-old TA-65-treated mice compared to age-matched untreated controls. JunB mRNA levels were normalized to actin. (E) Fold change in c-Myc mRNA levels 3 months post-treatment in different tissues of 2-year-old TA-65-treated mice compared to age-matched untreated controls. c-Myc mRNA values were normalized to actin. Student’s t-test was used for statistical comparisons. (F) Percentage of c-Myc-positive cells, quantified from at least four independent mice. Measurements were realized postmortem in cancer-free mice. Student’s t-test was used for statistical comparisons. At least five high-power fields (×100) were used per independent mice (around 3000 cells scored per mice, AxioVision was used for image analysis). (G) Representative IHC of c-Myc staining in either control or TA-65-treated 2-year-old female mice. (H) Hypothetical model of action of TA-65 based in ours and previous results.

Telomere attrition and the accumulation of short telomeres are parallel to the aging process in humans and mice, being a probable cause of the appearance of age-related pathologies (Harley et al., 1990; Canela et al., 2007; Jiang et al., 2008; Calado & Young, 2009). Short telomeres are therefore both an indicator and a possible cause of health-span decay with age either in humans and mice. Following the above-described results with MEFs, we set to address whether a dietary supplementation with TA-65 could similarly lead to detectable changes on telomere dynamics in vivo. To this end, we fed two cohorts of

**Dietary supplementation of TA-65 increases TERT expression in some tissues and rescues short telomeres in mice**

Together these results suggest that the mechanism of action of TA-65 in its capability to decrease the percentage of short telomeres, of ‘signal-free ends’, as well as of DNA damage, requires the presence of an active telomerase complex.

![Fig. 2 Continued.](image)
mature or old female mice (1 or 2 years old, respectively) with control vehicle (fruit mash) or vehicle plus TA-65 (final concentration of 25 mg kg$^{-1}$ body weight/day) for 4 months (scheme in Fig. 2A, and detailed information in Methods). Treated mice demonstrated a complete tolerance to the administration of the vehicle or vehicle+TA-65 as no deaths or other overt pathologies related to treatment were observed during this period. In line with this, body weight was maintained and comparable between the different mouse cohorts throughout the treatment period (Fig. S2).

It has been previously described that treatment of CD8$^+$ T lymphocytes with a similar telomerase activator compound (TAT2) leads to an 8-fold increase in human telomerase reverse transcriptase mRNA levels (Fauce et al., 2008). To follow the effects of TA-65 dietary supplementation in vivo, we examined mouse telomerase reverse transcriptase (mTERT) mRNA levels in different tissues from the 2-year-old TA-65-treated or control cohorts at 3 months post-treatment. Notably, TA-65 treatment of 2-year-old mice resulted in a significant 10-fold increase in mTERT mRNA (Fig. 2B) and protein (Fig. 2C) levels in the liver as determined 3 month post-treatment. Mouse telomerase reverse transcriptase mRNA levels were also modestly increased in other tissues from these mice including kidney, lung and brain, although these increases did not reach statistical significance (Fig. 2B). Of note, the same patterns were observed in the 1-year-old mouse cohort (Fig. S3A). Interestingly, increased levels of mTERT in the liver of both 1- and 2-year-old TA-65-treated mice correlated with an increase in mRNA levels of JunB (Figs 2D and S3A) and c-Myc (Figs 2E and S3A), two transcription factors regulated by the MAPK pathway (Gupta et al., 1993; Lefloch et al., 2008), which is a known potential mediator of TA-65 action (Fauce et al., 2008). Higher levels of c-Myc in the liver were confirmed by IHC in the 2-year-old group of mice, at the time of death (Fig. 2F,G). Of note, TA-65 did not alter significantly the levels of targets of the Wnt (CD44 and CyclinD1) or TGFβ (Fibronectin, Klf4, or p16) pathways (Fig. S4), further supporting that TA-65-dependent telomerase activation occurs through transcription factors regulated by the MAPK pathway, which may directly or indirectly regulate the mTERT promoter (hypothetical mechanism in Fig. 2H, based on our current findings and previous results (Wang et al., 1998; Greenberg et al., 1999; Chang & Karin, 2001; Inui et al., 2001; Takakura et al., 2005; Pericuesta et al., 2006)).

To address the in vivo effect of TA-65 treatment on telomerase-mediated telomere elongation, we measured telomere length in blood samples from the 1- and 2-year-old controls and TA-65-treated groups, 3 months after the dietary supplementation period ending. Telomere length was assessed from peripheral blood leukocytes by using a high-throughput (HT) Q-FISH technique optimized for blood samples (Canela et al., 2007). Average telomere length was not significantly increased in the 1- or 2-year-old TA-65-treated groups compared to the untreated controls (Fig. 3A,C). Interestingly, we observed a significant decrease in very short telomeres (telomeres below 2, 3 and 4 kb, Fig. 3B,D) in the 1- and 2-year-old TA-65-treated groups at 3 months post-treatment, indicating a significant and consistent capacity of TA-65 to promote rescue of short telomeres both in vitro (MEFs) and in vivo (mice). A similar scenario has been previously described in a study assessing the role of TA-65 in humans, where a reduced percentage of cells with short telomeres appeared concomitant with minimal effects in the mean telomere length (Harley et al., 2010).

**TA-65 treatment enhances health span in female mice**

Previous studies have demonstrated that the shortest telomeres are causal of reduced cell viability (Hemann et al., 2001b; Hao et al., 2005) and that a stable and enforced expression of telomerase leads to an improved health span, accompanied by an extension of lifespan, possibly through the rescue of short telomeres in mice (Tomas-Löba et al., 2008). As TA-65 influences the percentage of cellular short telomeres through the activation of telomerase, we were interested in addressing whether this compound could have an impact on health and/or lifespan in the treated mice.

The aging process can be evaluated by studying some of the so-called biomarkers of aging. One established indicator of aging in mice is glucose intolerance and insulin resistance, which increase with age (Bailey & Flatt, 1982; Guarante, 2006). Importantly, TA-65 administration during 4 months significantly improved the capacity to uptake glucose after a glucose pulse (area under the curve) in the 1-year-old treated mice compared to the control groups at 6 and 12 months post-treatment (Fig. 4A,D; Methods). Furthermore, 1-year-old TA-65-treated mice presented a tendency to show lower levels of blood insulin at 6 months post-treatment which, together with the glucose levels at fasting, resulted in a tendency to have a better homeostasis model assessment of insulin resistance (HOMA-IR) score at 6 months post-treatment (Fig. 4B,C) (Heikkinen et al., 2007). Of note, although we observed a better glucose uptake at 12 months post-treatment with TA-65 in the 1-year-old group (Fig. 4D), this was not accompanied by lower basal insulin levels or by a better HOMA-IR score; a similar situation was observed 6 months post-treatment in the 2-year-old TA-65-treated group (Fig. 4E-I). These findings may suggest that a discontinued TA-65 intake could result in an attenuation of some health-span improvements [a situation in agreement with previous observations (Fauce et al., 2008)], and/or that old mice are less refractory to TA-65 treatment.

Liver steatosis is caused by lipid accumulation within hepatocytes both in humans and in mice. Despite being a relatively benign condition, when combined with inflammation it may progress to serious liver disease (Feldstein et al., 2003; Higuchi & Gores, 2003). Although mouse liver steatosis models involve usually intake of a high-fat diet (and subsequent diet-induced obesity) (Pfluger et al., 2008), this condition may also occur in aged mice under standard diet conditions (Kelder et al., 2007). As expected, lipid droplets were found in liver sections of both control and TA-65-treated mice at the time of death (Fig. 4J).
Interestingly, control mice presented the strongest accumulation of fat in the liver at older ages comparing to the TA-65-treated cohorts, which, together with the previous results, could indicate a liver protective action of TA-65 (Fig. 4J).

Other well-established biomarkers of aging are the loss of the epidermal and subcutaneous adipose skin layers (Shimokata et al., 1989; Tomas-Loba et al., 2008). The weakness of the skin barrier associates with infections and deficient water exchange. TA-65 treatment resulted in a significant increase in subcutaneous fat content and epidermal layer in the 1-year-old group of mice (Fig. 5A,C) and representative image in Fig. 5B), but did not significantly change these parameters in the 2-year-old groups (Fig. 5A,C), compared to the untreated controls. In line with an improved epithelial fitness, TA-65 treatment increased the in vitro wound-healing capacity of keratinocytes (Fig. 5D) as well as significantly accelerated hair regrowth in vivo upon plucking of old mice (Fig. 5E and representative image in Fig. 5F). Moreover, the epidermis of TA-65-treated mice showed significantly more proliferating cells (Ki67-positive cells; Fig. 5G and representative image in Fig. 5H) together with significantly reduced numbers of TUNEL-positive apoptotic cells (Fig. 5I and representative image at Fig. 5J). Similar results were obtained in the lung (Fig. S5A–D) but not in the liver (Fig. S5E–H), suggesting that the capacity of TA-65 to stimulate proliferation in vivo may be tissue-dependent.

Bone loss, which results from the imbalance between osteoclast and osteoblasts, is also a common finding with increasing age both in mice and in humans, leading to age-related bone fragility (Ferguson et al., 2003). Bone density was improved in the 2-year-old TA-65-treated group compared to their controls without TA-65 supplementation (measurements at the time of death, Fig. 5K).

Previous findings demonstrated that TA-65 uptake leads to significant changes in blood or immune parameters in humans (Fauce et al., 2008; Harley et al., 2010). Table 1 summarizes the haematological analysis of either 1- and 2-year-old control mice compared to TA-65-treated groups. Although no significant dif-

At least six high-power fields (HPF, ×100) were used per independent mouse and around 2000 skin epidermis cells were scored per mouse. (H) Representative Ki67 immunohistochemistry images of skin epidermis (tail) from TA-65-treated or untreated (control) mice. (I) Percentage of TUNEL-positive (Apostag detection kit) cells in the epidermis (tail skin) of TA-65-treated or untreated (control) mice. Student’s t-test was used for statistical assessments. At least six HPF (×100) were used per independent mouse and around 2000 skin epidermis cells were scored per mice. (J) Representative TUNEL stained images of skin from TA-65-treated or untreated (control) mice. (K) Femur bone mineral density (BMD femur) measured at the time of death in the 2-year-old cohorts treated with or nontreated with TA-65.
much after the treatment period in the 1-year-old group, where the effect of TA-65 has been already partially lost. These results demonstrate that TA-65 per se can modestly but significantly enhance overall organ fitness of both mature (1 year old) and old (2 years old) female mice.

TA-65 intake does not impact on mean or maximum longevity of female mice
The known impact of telomerase in aging and cancer lead us to address whether TA-65 supplementation could have any beneficial or undesirable effects on mouse survival and cancer incidence, respectively. Recent evidences demonstrate that enforced expression of telomerase either from the germline (together with enforced expression of tumor suppressors) or ectopically in adult/old mice leads to a significant extension of both mean and maximum lifespan [(Tomas-Loba et al., 2008) and unpublished data].

Analysis of the Kaplan–Meier survival curves of control vs. TA-65-treated female mice demonstrated no significant effects of TA-65 intake on survival (Fig. 6A,B). Accordingly, TA-65 administration for 4 months did not change statistically the mean or maximal lifespan of female mice under our experimental conditions.

Fig. 5 Continued.
TA-65 does not increase cancer incidence

A disadvantage of mTERT potentiation could be associated with its capacity to favor the proliferation of cancerous cells in murine models (Gonzalez-Suarez et al., 2001; Artandi et al., 2002; Canela et al., 2004; McKay et al., 2008; Tomas-Loba et al., 2008; Rafnar et al., 2009). To address whether TA-65 supplemented diet had undesirable long-term side effects, we performed a pathological analysis of all female mice under treatment and controls at the time of death. We observed that TA-65-treated mice presented a similar incidence of malignant cancers at the time of death, with a tendency to show decreased incidence in TA-65-treated mice (Fig. 6C,D). Moreover, although we observed an increased incidence of cancer in the liver of TA-65-treated mice (were TA-65 treatment resulted in a 10-fold increase in TERT expression) compared to control mice, these differences did not reach statistical significance (Fig. 6D).

Discussion

Strategies to extend healthspan conditions with lifetime extension have been the target of scientific investigation for decades. From the preliminary studies describing the effects of caloric restriction, which evolve to detailed characterizations of pathways and potential targets resulting in recent conceivable treatments, the outcome has been continually focused in a healthier organismal living (Guarente & Kenyon, 2000; Hayflick, 2000; Kirkwood & Austad, 2000; Kenyon, 2010).

Here, we characterize a small-molecule compound (TA-65) extracted from the roots of a medicinal Chinese plant used, among other things, to ‘protect’ the immune system or ‘preserve’ the liver (Shen et al., 2006; Clement-Kruzel et al., 2008; Mao et al., 2009). We demonstrate here that TA-65 leads to a significant rescue of short telomeres through telomerase activation in MEFs haploinsufficient for the telomerase RNA component. Indeed, TA-65 treatment increases proliferation and mobilization potential of mouse keratinocytes in vitro, a situation mimicking telomerase overexpression (Greider, 1998; Cerezo et al., 2003). Recently, Fauce et al. (2008) demonstrated that TATZ, a similar molecule, have beneficial effects in the activation of CD8+ T lymphocytes from HIV-infected patients where they observe an increase in the proliferative potential and enhancement of cytokine/chemokine production.

The use of TA-65 as a treatment to improve health span in humans has been tested in past few years, where subjects took...
TA-65 elongates short telomeres and increases health span of adult/old mice, B. B. de Jesus et al. 13

part in an open label comprehensive dietary supplementation program, which included a TA-65 dose of 10–50 mg daily (Har-ley et al., 2010). Report analysis of the first treatment year has been recently released, demonstrating high tolerability and some beneficial effects in humans after treatment periods ranging from 3 to 12 months (Harley et al., 2010). We have now assessed the specific effects of TA-65 in a blinded study of two cohorts of 1-year-old (mature) or 2-year-old (old) female mice where an adjusted dose of TA-65 was administrated daily for 4 months. Similar to humans, TA-65 treatment in mice resulted in a similar rescue of short telomeres in leukocytes at 3 month post-treatment. Interestingly, we observed that, at least in mice, the liver is one of the main targets of TA-65 treatment, where it leads to a > 10-fold increase in TERT RNA levels compared to nontreated age-matched cohorts. Furthermore, this increase in mTERT mRNA levels is accompanied by increased c-Myc and JunB mRNA levels. These results enforce the previous idea that TA-65 regulates telomerase at the transcription level, probably through the regulation of the MAPK pathway (Fauce et al., 2008). Whether or not TA-65 could regulate post-transcriptionally the levels of telomerase in the liver or other tissues has not been assessed here or elsewhere, although this is improbable in the case of mouse telomerase because some mTERT post-translational modifications such as phosphorylation is mediated through the AKT pathway, which seems not to be influenced by TA-65 (Kang et al., 1999; Gomez-Garcia et al., 2005; Fauce et al., 2008).

We further show here that TA-65-dependent telomerase activation results in a better organ fitness as demonstrated by the improved scores at the glucose tolerance test. These enhancements could be related to the TA-65-dependent ERK pathway activation in the liver and subsequent telomerase expression, which have been shown to mediate the glucose tolerance and insulin response (Tomas-Loba et al., 2008). Moreover, ERK signal is silenced by the activation of the p38 MAPK, which responds to external damage signals arising usually with aging progression and oxidative damage accumulation, and result in age-related insulin insensitivity and glucose intolerance (Kryiakis & Avruch, 2001; Au et al., 2003; Li et al., 2007; Bluhner et al., 2009). TA-65-supplemented mice also present modest but significant enhancement of the subcutaneous and epidermal thickness, as well as higher bone density, representative of an overall fitness status improvement. A similar situation has been previously observed in mice overexpressing the telomerase catalytic subunit (Tomas-Loba et al., 2008). Analysis of the blood parameters also demonstrated that 2-year-old TA-65-treated mice present higher levels of RBC and hemoglobin compared to the control cohorts. The decrease in such parameters is a regular situation experienced during aging progression in healthy old mice and could be related to RBC fragility and deficient regulation of the stem cell pools (Ewing & Tauber, 1964; Finch & Foster, 1973; Tyan, 1980, 1982ab; Xing et al., 2006). Importantly, improved health span of TA-65-treated mice is not accompanied by increased cancer incidence, which may be related to the fact that TERT levels are very modestly increased in all tissues tested except for the liver. Alternatively, telomerase enhancement in adult (1 year old) or very old mice (2 year old) may have beneficial effects without increasing cancer incidence because older organisms are more refractory to proliferative stimuli.

Finally, the results obtained here with MEFs haploinsufficient for telomerase activity suggest that the beneficial effects of TA-65 treatment in rescuing critically short telomeres and DNA damage are likely mediated by the telomerase pathway. This goes in line with recent data from our group showing that systemic mTERT overexpression from the germline leads to rescue of short telomeres and of DNA damage and to protection from aging-associated pathologies (Tomas-Loba et al., 2008). Similarly, re-expression of TERT in mice that were already aged because of TERT deficiency can rescue telomere length and delay aging in these mice (Jaskelioff et al., 2010). Finally, TERT increase expression may also have beneficial effects on aging through its potential ability to activate the Wnt pathway (Park et al., 2009).

Here, we provide evidence on the role of TA-65 in a healthy aging improvement but not survival (either mean or maximum longevity) in female mice. The balance between health enhancement and longevity do not always correlate. Indeed, if a long-lived mammalian organism presents regularly health benefits (Berrymann et al., 2008; Tomas-Loba et al., 2008), the opposite as shown to be potentially untrue (Herranz & Serrano, 2010). Of importance is the fact that we feed our mice cohorts for a limited period of time (4 months), being the impact of the compound shown to be partially lost during the absence period (Fauce et al., 2008); even though, we show that some phenotypic rescues (such as the hair regrowth) can be maintained longer after TA-65 uptake conclusion. We cannot discard that a longer or constant dietary supplementation of TA-65 could also impact on lifespan or cancer. In conclusion, here we described new findings on the potential therapeutic use of TA-65, delineating for the first time its mechanism of action and organismal response.

Methods

Formulation of TA-65

TA-65 was obtained from TA Sciences. TA-65 is a > 95% pure single chemical entity as judged by HPLC and NMR (data not shown), which was isolated from a proprietary extract of the dried root of *Astragalus membranaceus* (Harley et al., 2010). TA-65 was dissolved in DMSO at 1- or 10-mM stock concentration (1000× final concentration).

Mice, cells, and treatments

All G2 Terc−/− and Terc−/− mice used in this study were of the same identical genetic background (C57BL6). Third-generation G3 Terc−/− and G3 Terc−/− littermate mouse embryos were derived from crossing G2 Terc−/− with Terc−/− mice (Fig. 1A). Genotyping was performed by Southern blotting as described.
TA-65 elongates short telomeres and increases health span of adult/old mice, B. B. de Jesus et al.

(Blasco et al., 1997). Mice were maintained at the Spanish National Cancer Centre (CNIO) under specific pathogen-free conditions in accordance with the recommendations of the Federation of European Laboratory Animal Science Associations.

Mouse embryonic fibroblasts were prepared from day 13.5 embryos as described (Blasco et al., 1997). Two independent TA-65 treatments were performed using independent MEF cultures. G3 Terc−/− and G3 Terc+/+ primary MEF (passage 1) were cultured for 6 days in Dulbecco’s modified Eagle’s medium (Gibco, Paisley, UK) supplemented with 10% fetal bovine serum and antibiotic/antimycotic at 37 °C/5% CO2. Fresh TA-65 was added to the media at a final concentration of 1 or 10 μM every 24–48 h, along with change of media, and cells were passaged at day 2 and 5. Control cells were treated with 0.1% DMSO.

Aged cohorts of female mice were obtained directly from Harlan Laboratories. Both 1- and 2-year-old groups were aged under standard conditions and present 100% C57BL/6J/OlaHsd background. Mice were conditioned in a pathogen-free area of CNIO after arrival, in accordance with the recommendations of the Federation of European Laboratory Animal Science Associations. Half of the mice were supplemented with 25 mg of TA-65 per kg of mouse body weight per day, mixed in 100 μL of fruit mash, for 4 months. Fruit mash alone was supplemented to the control cohorts (100 μL, with the same periodicity as treatment groups). Mice were daily inspected by an authorized animal facility supervisor, before and after TA-65 treatment. Mice were sacrificed when presenting signs of illness or tumors in accordance with the Guidelines for Humane Endpoints for Animals Used in Biomedical Research.

Telomere repeat amplification protocol

Telomerase activity in G3 Terc−/− and G3 Terc+/+ MEF was measured by TRAP as described previously (Blasco et al., 1997). Protein extracts of HCT116 cells served as a positive control. As negative controls, protein extracts were treated with 5μg RNase for 10 min at 30 °C before performing the TRAP assay. Radioactive gels were exposed to BioMax MS films (Kodak) for at least 12 h at ~80 °C. Quantification was performed on digitalized films, using IMAGEJ software (NIH). The mean intensity of each lane after background subtraction was calculated, normalized by the dilution factor of the applied protein extract, and expressed as folds relative to the corresponding DMSO-treated cells.

Q-FISH and HT QFISH

At 70% confluence, primary MEFs (passage 3) were incubated with 0.1 mg mL−1 Colcemide (Gibco) at 37 °C for 4 h to induce metaphases. Cells were then harvested and fixed in methanol/acetic acid (3:1). Metaphases were spread on glass slides and dried overnight, and Q-FISH was performed using a PNA telomeric probe as described previously (Herrera et al., 1999; Samper et al., 2000).

Metaphases were analyzed with a fluorescence microscope (DMRA2; Leica, Wetzlar, Germany), and images were captured with a COHU CCD camera (San Diego, CA, USA) using the Leica Q-FISH software. Fluorescence intensity of telomeres was quantified by spot IOD analysis using the TFL-TELO software (provided by P. Landsdorp, Vancouver, Canada) and normalized to the fluorescence intensity of fluorescent beads (Molecular Probes, Carlsbad, CA, USA).

High-throughput-quantitative telomere fluorescence in situ hybridization was performed as previously described (Canela et al., 2007). Briefly, blood was extracted at the indicated time points after TA-65 treatment was finished. Peripheral blood leukocytes were plated on a clear bottom black-walled 96-well plate. Telomere length values were analyzed using individual telomere spots (> 5000 per sample) corresponding to the specific binding of a Cy3-labeled telomeric probe. Fluorescence intensities were converted into kilobase as previously described (Mcllrath et al., 2001; Canela et al., 2007).

Quantitative real-time RT–PCR

Total RNA from liver was extracted with Trizol (Life Technologies). Samples were treated with DNase I before reverse transcription using random primers and Superscript Reverse Transcriptase (Life Technologies), following the manufacturer’s guidelines. The primers used were as follows: Actin-For: GGACACACACTCTTACAATG; Actin-Rev: GTGGTGGTGAACGTGTAG; TERT-For: GGATTGCCACTGCTCCG; TERT-Rev: TGCTGACCTCCTCTTGTGAC; JunB-For: AGC CTC CCT CCG TCT ACA CCA; JunB-Rev GCC GCT TTC GCTCCA CTT TGA TG; c-Myc-For: ATGCCCTCTACGCTGACCTC; c-Myc-Rev: CGCAAGATGGATGGAGAGCA; CyclinD1-For: TGC GCC CTC GTT CAT TAC TC; CyclinD1-Rev: ATCTTAGAGGCACAGCAATGC; CD44-For: CAGCCCTACTGGAATGGAGT; CD44-Rev: GGAGTCCCTTGAGATGGTCA; p16-For: CGTACCCCGATTCAGGTGAT; p16-Rev: CGTACCCCGATTCAGGTGAT; Klf4-For: GCGAACTCACAGCGAGAAACC; Klf4-Rev: TGGCTTCCTCTCTTCTCCAGACA; Fibronectin-For: TACCAAGGTCAATCCACCCC; Fibronectin-Rev: CAGATGCACAAAGAAAGCAGAG.

Histological analyses

We performed c-Myc (sc-764; Santa Cruz biotechnology) Ki67 (M7249, clone TEC-3) and TUNEL (ApopTag Detection Kit) staining on paraformaldehyde-fixed, paraffin-embedded sections (Axiowision and Scion Image software were used for image analysis; quantitation of immunostaining was determined by counting the number of peroxidase stained nuclei over the total

Aging Cell © 2011 Blackwell Publishing Ltd/Anatomical Society of Great Britain and Ireland
number of haematoxylin-stained nuclei) and oil red O staining (fat cells) on liver frozen sections. Samples were processed and acquired under identical conditions.

For complete blood cell counts, we collected blood samples just before euthanasia. Data represents information collected from, at least, five mice. Counts were done using an Abacus Junior Vet System.

Glucose tolerance tests, insulin levels, and HOMA-IR

Glucose tolerance test and analysis were performed as described elsewhere (Moynihan et al., 2005). Mice were fasted for at least 6 h and injected intraperitoneally with a 50% dextrose solution (2 g kg⁻¹ body weight).

Blood insulin levels were measured with an Ultra-Sensitive Mouse Insulin ELISA Kit (Crystal Chem Inc. no 90080), following the manufacturers protocol. Mice were fasted for at least 6 h prior to blood insulin analysis. HOMA-IR was calculated as previously described (Matthews et al., 1985; Heikkinen et al., 2007).

Bone density, skin measurements, and cell migration

Bone mineral density was measured in the femur of female mice postmortem using a dual energy X-ray absorptiometry scan device. Subcutaneous fat and epidermal layers measurements were performed as previously described (Tomas-Loba et al., 2008). ImageJ software was used for skin length measurements.

Cell migration assays were performed on neonatal human epidermal keratinocytes (HEKn). Briefly, a confluent monolayer of HEkN was scraped with a sterile pipette tip. Migration into the wound was scored after 24, 48, or 72 h in the presence of DMSO or TA-65 (10 μM). ImageJ software was used for length measurements.

Hair regrowth assay was performed and quantified as previously described (Matheu et al., 2007). Briefly, dorsal hair was removed by plucking from a square of approximately 1.5 x 1.5 cm. Hair regrowth was scored two weeks later and a semi-quantitative assessment using an arbitrary scale from one to four (where four represents complete hair regeneration).

Statistical analyses

Statistical significances were calculated using GraphPad Prism 5 software. An unpaired student’s t-test was used to calculate statistical significances of telomerase activity (TRAP), mRNA expression levels, protein levels, IHC quantification, glucose tolerance, insulin levels, HOMA-IR, skin measurements, and bone mineral density. Statistical analysis of hair regrowth experiments was assessed with Fisher’s exact test. Statistical significances of differences in overall telomere length were determined by Wilcoxon-Mann-Whitney rank sum test. For statistical analyses of percentage of short telomeres and pathological analysis at the time of death, a chi-square test was used. Finally, a Log rank test was used for survival comparisons between cohorts.

Acknowledgments

We thank R. Serrano for mouse care and J. Flores for pathology analyses. We thank Comparative Pathology Unit at CNIO for technical assistance. M.A. Blasco’s laboratory is funded by the Spanish Ministry of Science and Innovation (MICINN), the European Union (GENICA, TELOMARKER), the European Research Council (ERC Advance Grants), the Körber European Science Award and the Fundacion Lilly Preclinical Award to M.A. Blasco. Maria A. Blasco acts as consultant and holds stock in Life Length, S.L., a biotechnology company based on measuring telomeres as an indication of health status and biological age of samples.

Author contributions

M.A.B conceived the idea. B.B. performed most of the experiments of the paper. K.S. performed the TA-65 administration and performed the analyses shown in Figs 1D–G and 5D. E.V. performed telomere length determinations (Fig. 3). A.T. performed the TRAP assays (Figs 1B and S1). M.A.B and B.B. wrote the paper.
